### ÖSSZEFOGLALÓ.

Két 100x100 méteres területet, egy erdőt és egy vegyes ültetvényt vizsgáltunk LiDAR ponttámaz alapján. A Progressive Morphological Filtering (PMF) és a Local Maximum Filtering (LMF) módszerek 257 fát azonosítottak az erdőben (módszertől függően) részben véletlenszerű, részben szabályos, 47-et a vegyes területen klaszteres eloszlással. A sűrűségmérések és legközelebbi szomszédok távolságának azonosítása G- és K-statisztikával. Monte Carlo-módszerrel és kvadrátpróbával jelentős különbségeket mutattak a fák eloszlásában, s jól jelezték a területek jellege közötti eltéréseket. Az alkalmazott módszer alkalmas az erdőterületek anomáliáinak azonosítására is.

**ABSTRACT.** This study processed two 100x100m areas from LiDAR dataset: a forest and a mixed forest-plantation. Progressive Morphological Filtering (PMF) and Local Maximum Filtering (LMF) methods identified 257 trees in the forest and 47 in the mixed area, showing (depending on the method) partly random, partly regular spacing in the forest and clustering in mixed areas. The density assessments and nearest-neighbour evaluations with G statistic, K statistic, Monte Carlo method, and quadrat tests revealed a significant difference in tree distribution, highlighting the effectiveness of these methods for detecting spatial patterns in diverse forest environments, too.

## 1 Introduction

The accurate identification of individual trees from LiDAR (ALS) measurements is a critical issue in forestry geoinformatics and statistics. However, the applicability of the frequently used

local maxima method [21] for tree identification is significantly influenced by the quality and preprocessing of data, as well as the type and structure of the forest [4]. The problem can be relatively simply stated: even the best and most widely adopted methods currently available are not sufficiently reliable, and often, results considered acceptable are not truly satisfactory [5]. The variable effectiveness of ITD (individual tree detection) methods also impacts the estimation of other metrics [9].

Several attempts have been made to address these issues. Rasterizing the point-based method can reduce the number of errors under certain conditions [17]. It can be satisfactory within a narrow scope but are limited in their applicability for surveying "unknown" forest areas, which is essentially the ultimate goal. Machine learning methods [12], Monte Carlo methods [1], principal component analysis [8], object-based labelling [15], and optimization methods [18] can predict and sometimes reduce the error magnitude for specific tree and forest types, but this does not necessarily imply that these methods can be generalized to most forest types. Resizing the TWS (tree window size) used in the analysis has led to more usable results in some forest types [13], but this also does not seem to be a generalizable method. Using the L function for refining detections appears to be a more general method [11], but the applied procedure is still not entirely independent of the expected and known results from field reference data. Of course, improving technical conditions, such as using high-density, close-range, multispectral LiDAR recordings [6], can also contribute to increasing the efficiency of the procedure.

In this article, an attempt is made to provide an example of how to outline a procedure based on the principles of nearest-neighbour distances without relying on precise reference data. Rather than focusing on the exact identification of individual trees, this method assesses the overall characteristics of the forest. This approach enables the detection and monitoring of specific "anomalies" within the forest using almost exclusively LiDAR imagery, thus facilitating rapid and efficient surveys.

## 2 Materials and methods

### 2.1 Data

The data described in Table 1. serve as the source for analysis. This LiDAR dataset was gathered by NCALM for Paula Figueiredo at North Carolina State University [14].

Features	Forest	Mixed vegetation
Horizontal Coordinates	WGS84 / UTM Zone 17N Metres [EPSG: 32617]	
Vertical Coordinates	Ellipsoid	
Number of Points	800743	528590
$X_{\min}, Y_{\min}$	490915, 4038800	491825, 4038310
$X_{\max}, Y_{\max}$	491015, 4038900	491925, 4038410

Table 1. Features of LiDAR datasets

The first LiDAR point cloud represents a purely forested area, while the second one depicts a forest patch and a plantation separated by a road. (Figure 1.) Both areas are 100 by 100 metres in size. Similar to common field conditions, we have a general overview of the area's characteristics, but we lack precisely surveyed reference data, such as the exact locations of the vegetation (trees) [20].

Figure 1. Vegetation areas

## 2.2 Canopy and tree detection

For ground classification, a Progressive Morphological Filter (PMF) was utilized. The original raster-based method [22] was modified by the developers of the R `lidR` package [19] used for data processing transforming it into a point-based approach [16]. During this process, the default values (window size = 3, threshold = 5) were used.

After ground classification, the digital terrain model (DTM) was created using the kriging method, which is more accurate but more resource-intensive than the commonly used triangulation method. Kriging is the most sophisticated approach, employing advanced geostatistical interpolation techniques that consider the spatial relationships and distances between the returns. Height normalization was ensured using point cloud-based normalization method. This model is superior in terms of computational accuracy by normalizing with a continuous terrain instead of a discretized terrain.

In the next step, the canopy height model was created using a point-to-raster method.

From this model, the coordinates of individual trees, along with their corresponding height values, were computed using a Local Maximum Filter (LMF) with window size = 5. During each step, various other methods were considered, but upon testing, these methods yielded essentially identical results [20].

## 2.3 Spatial statistical analysis

The density-intensity of tree locations was visually analysed. Subsequently, the nearest-neighbour distances and, more generally, the pairwise distances within each sample plot were analysed as follows [2].

The cumulative distribution function of the nearest-neighbour distances for a regular point in the point (tree) pattern in a stationary point process  $\mathbb{X}$  is

$$G(r) = \mathbb{P}(d(u, \mathbb{X} \setminus \{u\}) \leq r \mid u \in \mathbb{X}),$$

where  $u$  is a random location, and  $d(u, \mathbb{X} \setminus \{u\})$  is the shortest distance between  $u$  and the points of the  $\mathbb{X}$  pattern, excluding  $u$ .

The observed distribution function for the distances to the measured nearest neighbours is

$$G^*(r) = \frac{1}{n(\mathbf{x})} \sum_i \mathbf{1}\{t_i \leq r\}.$$

Edge corrections based on the empirical cumulative distribution function is

$$\hat{G}(r) = \sum_i e(x_i, r) \mathbf{1}\{t_i \leq r\}. \quad (1)$$

The  $e(x_i, r)$  edge correction weight in the above equation ensures the approximate unbiasedness of  $\hat{G}(r)$ .

The distribution function of the nearest-neighbour distances in a homogeneous Poisson point process with intensity  $\lambda$  is

$$G_{\text{pois}}(r) = 1 - \exp(-\lambda\pi r^2). \quad (2)$$

In the case where  $\hat{G}(r) > G_{\text{pois}}(r)$ , the pattern is considered clustered, while when  $\hat{G}(r) < G_{\text{pois}}(r)$ , the pattern is classified as regular. In addition to the theoretical Poisson distribution, the Hanisch estimate [7], the border-corrected estimate, and the Kaplan-Meier estimate [10] for  $\hat{G}(r)$  are used.

The biased patterns of  $s_{ij} = \|x_i - x_j\|$  pairwise distances, namely the overrepresentation of smaller distances, can be attributed to reasons similar to those mentioned before. The expected number of other points of the process within a distance  $r$  from a typical point of the process is denoted as

$$K(r) = \frac{1}{\lambda} \mathbb{E} [n(\mathbb{X} \cap b(u, r) \setminus \{u\}) \mid u \in \mathbb{X}].$$

The anticipated number of points within the region  $b(u, r)$  is  $\lambda\pi r^2$ . For a homogeneous Poisson process, this is independent of the intensity.

$$K_{\text{pois}}(r) = \pi r^2. \quad (3)$$

Estimators for this value are adjusted and normalized as empirical distribution functions of the pairwise distances, which is

$$\hat{K}(r) = \frac{1}{\hat{\lambda}^2 \text{area}(W)} \sum_i \sum_{j \neq i} \mathbf{1}\{\|x_i - x_j\| \leq r\} e(x_i, x_j; r), \quad (4)$$

where  $e(u, v, r)$  is the edge adjustment factor. If  $\hat{K}(r) > K_{\text{pois}}(r) = \pi r^2$ , clustering is observed, while if  $\hat{K}(r) < K_{\text{pois}}(r) = \pi r^2$ , a regular pattern is indicated.

In addition to the theoretical Poisson model  $K(r)$ , boundary-corrected estimation, translation-corrected estimation, and isotropic correction estimation are computed.

Numerous other metrics and procedures are associated with the statistics of spatial points, but these appear to be the most important. The previous findings must also be tested using inferential statistical methods.

Given the significance of the K statistic even within this narrow scope, the results of the K statistic were tested using a Monte Carlo method suitable for spatial data [3].

A key question in the  $K$  statistic is whether there is a difference between  $\hat{K}$  and  $K_{\text{pois}}$ .

The initial hypothesis is

$$H_0 : \text{The observed point set is a representation of a random spatial process.} \quad (5)$$

The reference curve for the procedure was the  $K$  function under complete spatial randomness (CSR).  $M$  independent simulations (with  $M = 39$ ) for a two-sided test at a 5% significance level, as  $\alpha = \frac{2}{M+1}$  were run for the study regions  $W$ . The estimated  $K$  functions  $\hat{K}^{(j)}(r)$  for

$j = 1, \dots, M$  were calculated for each realization. The lower ( $L$ ) and upper ( $U$ ) pointwise envelopes for these simulated curves are

$$L(r) = \min_j \hat{K}^{(j)}(r)$$

and

$$U(r) = \max_j \hat{K}^{(j)}(r).$$

For a fixed  $r$ , the probability of  $K_b(r)$  exceeding the envelope  $[L(r), U(r)]$  for simulated curves indicates rejection of the null hypothesis of a uniform Poisson process, with a significance level of  $\alpha = \frac{2}{M+1}$ . Alternatively, using pointwise order statistics provides a test with exact size  $\alpha = \frac{2k}{M+1}$  for the  $k$ -th largest and  $k$ -th smallest values.

In addition to the Monte Carlo test, a quadrat test was conducted. This test does not rely on the L-K statistic, making it suitable for verifying our previous results. The study regions are divided into equal-sized quadrats (2x2), and the number of points within each quadrat is counted. Under the  $H_0$ , the points (trees) follow a homogeneous Poisson process, meaning they are randomly distributed, similarly to the previous null hypothesis. The observed frequency distribution of points per quadrat is compared to the expected Poisson distribution. The chi-square test statistic is used to quantify the difference is

$$\chi^2 = \sum_{i=1}^n \frac{(O_i - E_i)^2}{E_i},$$

where  $O_i$  is the observed frequency and  $E_i$  is the expected frequency.

### 3 Results

During the process, 257 trees were identified in the forested area and 47 trees in the mixed vegetation area (Figure 2).

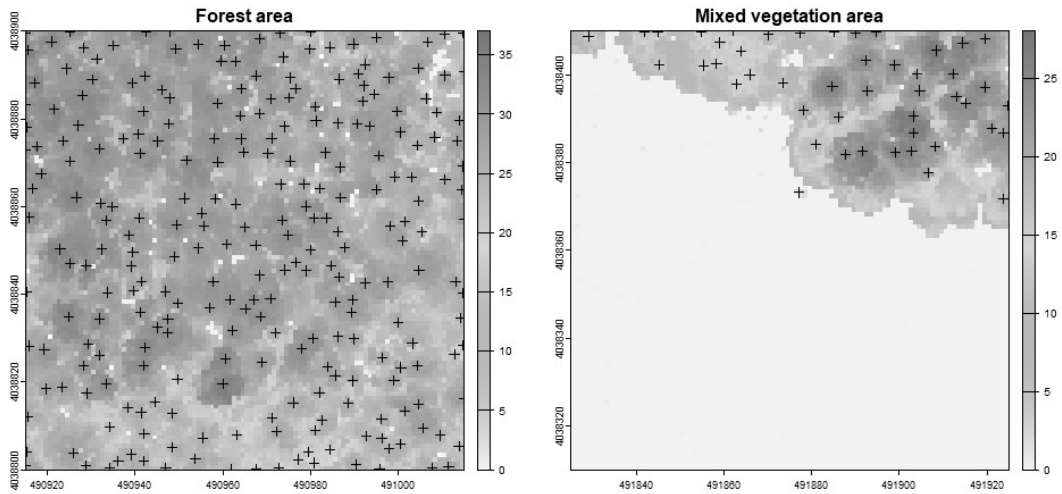

Figure 2. Canopy and trees

The estimation of  $G(r)$  from (1) suggests that the pattern of trees in the forest area is regular. Specifically,  $G(r) = 0$  for  $r \leq 2.5$  metres, indicating that there are no nearest-neighbour distances less than 2.5 metres. The difference between the two plant covers is reflected in the

$G$  statistic (1) and (2). In the second area, there are no trees within a distance of 2.5 metres as well, but for  $r \geq 3.5$ , the forest exhibits strong clustering characteristics (Figure 3).

Figure 3.  $G$  statistic

Unlike what was observed with the  $G$  statistic, the  $K$  statistic (3) and (4) indicates that in the fully forested area, a pattern similar to the Poisson model can be seen. However, in the mixed vegetation area, clustering is observed, similar to previous findings (Figure 4).

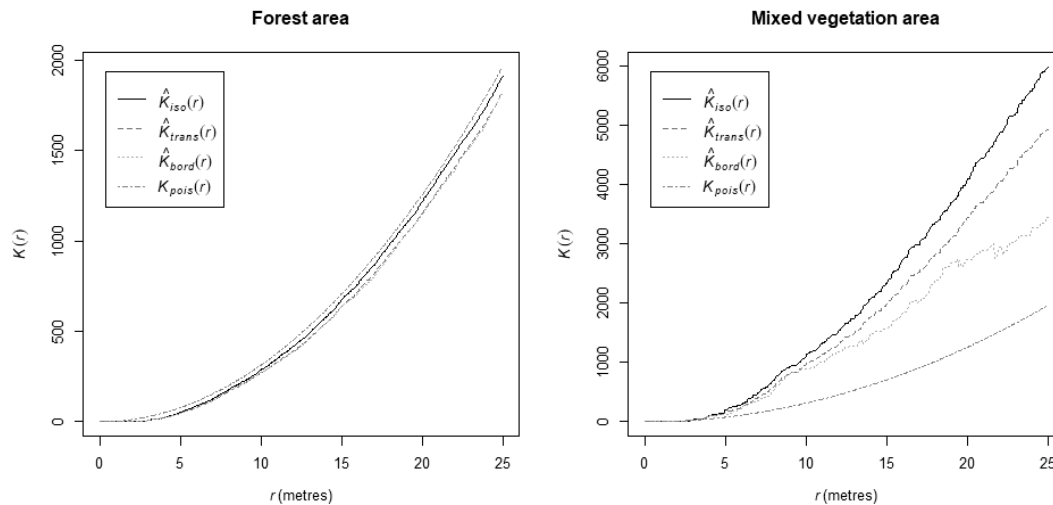

Figure 4.  $K$  statistic

In the first case,  $H_0$  from (5) of randomness is not definitively rejected, whereas in the second case, it is unequivocally rejected. This is consistent with our prior findings (Figure 5).

The obtained result was confirmed by the  $\chi^2$  test (Table 2 and Figure 6).

Area	$\chi^2$	$df$	$p$ -value
Forest Area (2x2)	2.2529	3	0.9568
Mixed Vegetation Area (2x2)	62.362	3	$3.678 \times 10^{-13}$

## 4 Conclusions

While the current models for individual tree identification using LiDAR data still require refinement, the incorporation of known field data and advanced statistical methods like  $G$  and  $K$  statistics holds promise for improving survey efficiency and accuracy. The continued development and validation of these models are essential for their widespread adoption in forestry applications, particularly in the context of sustainable forest management and conservation.

The comparison of the two areas using applied identification and statistical methods has demonstrated that, essentially, valid conclusions can be drawn about the trees covering the area even without field surveys, given a cost-effective technological background. We believe that the refinement of models beyond the results of field surveys and the more precise identification of trees is often impractical, as such methods are generally not generalizable. Reverting to random distributions and filtering significant anomalies alongside the methods we use offers a limited but important means of drawing conclusions in forestry and the timber industry. The applied method provides an opportunity to identify anomalies that have occurred in the forest area (tree mortality, tree cutting, natural damage) based on previous recordings.
